

The Sharpe Stability Ratio in Tactical and Static Asset Allocation Backtests: Evidence from 173 Published Strategy Variants

Laurent Bonherbe, BestFolio Research

Working paper, version 0.3, 6 September 2026

Abstract

A backtested Sharpe ratio summarises how large a strategy's risk-adjusted return was over a sample, not how it was distributed across the sample. We apply the Sharpe Stability Ratio (SSR) of Bajo Traver and Rodriguez Dominguez (2026), the mean of a rolling 36-month Sharpe ratio divided by a heteroskedasticity and autocorrelation consistent estimate of its long-run standard deviation, to 173 tactical and static asset allocation strategy variants published on one backtesting platform, with completed monthly histories of 18 to 106 years ending in August 2026. We report a fixed-bandwidth descriptive version of the statistic and treat it as a ranking aid. Three descriptive findings follow. First, SSR is imperfectly rank-correlated with the Sharpe ratio (0.67) and with the platform's Deflated Sharpe Ratio (0.61): of 146 variants whose Deflated Sharpe Ratio is at least 0.90, 54 have an SSR of at least 0.5 and 92 fall below it. Second, estimated SSR rankings depend strongly on the evaluation period. Aggregate rankings are stable across rolling windows and bandwidths (rank correlations 0.94 to 0.99), but across calendar decades the cross-sectional rank correlation between adjacent periods is -0.04 , -0.43 and 0.08 , and the S&P 500's own SSR moves from 0.15 in the 2000s to 1.63 in the 2010s. Third, the association between reported turnover and SSR is positive (rank correlation 0.31; 0.23 within tactical variants), and static allocations have the lowest median SSR. A moving block bootstrap places every percentile interval above zero and no 5th percentile above 0.5. We document the estimator, the choices behind it, and their consequences.

1. Introduction

The Sharpe ratio remains the dominant summary of a backtest. Two strategies with the same Sharpe ratio over the same sample can nonetheless have earned it in very different ways: one steadily, the other in a handful of episodes that happened to fall inside the sample. A full-sample inference statistic does not directly summarise the path of rolling Sharpe estimates. The Probabilistic Sharpe Ratio (Bailey and López de Prado, 2012) assesses whether an observed Sharpe ratio is distinguishable from a benchmark given the sample length and the higher moments of returns. The Deflated Sharpe Ratio (Bailey and López de Prado, 2014) compares it with a model-based expected maximum among the trials that produced it. Neither describes how the estimate evolved over time.

Bajo Traver and Rodriguez Dominguez (2026) propose the Sharpe Stability Ratio (SSR) for that purpose. They treat the rolling Sharpe ratio as a time series, show that overlapping windows induce autocorrelation that a naive standard deviation understates substantially (reported naive-to-HAC standard deviation ratios of 0.19 to 0.29), and define stability as the mean of the rolling series divided by a heteroskedasticity and autocorrelation consistent (HAC) estimate of its long-run standard deviation. Their empirical work covers seventeen hedge fund style indices over 29 years.

This paper applies the SSR to a different population: rules-based asset allocation strategies whose histories are simulated rather than lived. The sample is the published catalog of BestFolio, a tactical asset allocation (TAA) research platform, comprising 173 strategy variants with at least ten years of completed monthly history, most of them reconstructions of published models (Faber, 2007; Antonacci, 2014; Keller and Keuning, 2016, 2017, 2018, 2022, 2023, among others) and the static allocations investors compare them with. The histories are long, 486 months at the median and up to 1,274 months, and every variant is scored on the same month-end series with the same execution assumptions. We extend the application to this catalog, examining sensitivity to the evaluation period, retrospective rank persistence across decades, and the association with reported turnover. The platform also publishes a Deflated Sharpe Ratio for each variant, which permits a descriptive comparison of its credibility scores with the estimated SSR values.

Our findings are descriptive and conditional on the estimator we use. SSR values range from 0.15 to 0.98 across the 173 variants, with a median of 0.44. SSR is imperfectly rank-correlated with the Sharpe ratio (0.67) and with the Deflated Sharpe Ratio (0.61). Tactical variants have a higher median SSR than static ones (0.45 against 0.37), and monthly-rebalanced strategies a higher median than daily or annually rebalanced ones. The unadjusted association between reported turnover and SSR is positive. Aggregate rank correlations are high across the tested rolling windows and bandwidths, although individual variants can move by as much as 49 places between bandwidths. Across four calendar subperiods the cross-sectional rank correlation between adjacent periods is -0.04 , -0.43 and 0.08 , and the S&P 500's own SSR moves from 0.15 in the 2000s to 1.63 in the 2010s. A moving block bootstrap places every variant's 95 percent percentile interval above zero and no variant's 5th percentile above 0.5.

Section 2 relates the SSR to the literature it extends. Section 3 describes the data, the platform's conventions and the sample restrictions. Section 4 states the estimator and the choices behind it. Section 5 presents the cross-sectional results, Section 6 the period sensitivity and robustness analysis, Section 7 the joint view with the Deflated Sharpe Ratio, and Section 8 the turnover results. Section 9 discusses limitations and Section 10 concludes.

2. Background

2.1 Sharpe ratio inference

Lo (2002) derived the asymptotic distribution of the Sharpe ratio estimator under independent and identically distributed returns, treated stationary returns and time aggregation, and formulated the serially correlated case in HAC and GMM form. Mertens (2002) gave the estimator's variance under independent but non-normal returns, and Opdyke (2007) showed that the same expression holds under stationary and ergodic returns and extended it to comparisons of Sharpe ratios. Bailey and López de Prado (2012) built the Probabilistic Sharpe Ratio on that variance: an inferential score, under its assumptions, for whether the true Sharpe ratio exceeds a benchmark given the estimate, the sample length, and the skewness and kurtosis of returns. Ledoit and Wolf (2008) proposed HAC standard errors and a studentized time-series bootstrap for comparing Sharpe ratios under dependent returns. López de Prado, Lipton and Zoonekynd (2026) provide a closed-form variance under first-order autocorrelation and non-normality,

$$\sigma^2[\widehat{SR}] = \frac{1}{T} \left(\frac{1+\rho}{1-\rho} - \frac{1+\rho+\rho^2}{1-\rho^2} \hat{\gamma}_3 SR + \frac{1+\rho^2}{1-\rho^2} \frac{\hat{\gamma}_4 - 1}{4} SR^2 \right),$$

where ρ is the lag-one autocorrelation of returns, $\hat{\gamma}_3$ the skewness and $\hat{\gamma}_4$ the kurtosis. For the monthly return series studied here the correction is small: the median lag-one autocorrelation across the 219 active variants is -0.03 (tenth and ninetieth percentiles -0.09 and $+0.03$), and recomputing each variant's Deflated Sharpe Ratio with this variance (using $T - 1$ in the denominator, as the platform does) changes scores by between -0.018 and $+0.021$; four variants cross the platform's 0.90 threshold, three of them published and all upward. The correction is therefore not material to the rankings, although it can move threshold classifications at the margin.

The Deflated Sharpe Ratio (Bailey and López de Prado, 2014) replaces the benchmark of the Probabilistic Sharpe Ratio with the expected maximum Sharpe ratio among K trials, given the cross-sectional variance of Sharpe ratios across those trials. It compares the observed Sharpe ratio with a model-based expected maximum under the assumed no-skill trial distribution. The 2014 paper already discusses dependent trials and an effective number of independent trials; the 2026 paper retains the expected-maximum benchmark while rescaling the standard error of the maximum by the standard deviation of the maximum of K standard normal variables. The platform's published score follows the 2014 formulation, which we take as given here. These statistics describe the full-sample estimate; in the terminology of Bajo Traver and Rodriguez Dominguez (2026) they are point-in-time, and say nothing about how the estimate was distributed across the sample.

2.2 The Sharpe Stability Ratio

For a return series $r_1, \dots, r_T$ and a window τ , Bajo Traver and Rodriguez Dominguez (2026) define the rolling Sharpe process $Z_t = \hat{r}_{t,\tau} / \hat{\sigma}_{t,\tau}$ for $t = \tau, \dots, T$, with the sample mean and sample standard deviation over the trailing τ observations. The structural Sharpe Stability Ratio is

$$SSR_0 = \frac{\mu_Z}{\sigma_\infty(Z)},$$

the population mean of the rolling process divided by its long-run standard deviation, with feasible analogue $\widehat{SSR}_0 = \hat{Z} / \hat{\sigma}_{HAC}(Z)$. Their Proposition 3.1 shows that under independent returns a rolling statistic inherits a mechanical autocorrelation $\rho_k \approx 1 - k/\tau$ for lags $k < \tau$ and zero beyond, so that the naive standard deviation of Z captures only approximately one fifth to three tenths of its long-run counterpart in their simulations. The HAC estimator is the Newey and West (1987) form with a Bartlett kernel,

$$\hat{\sigma}_{HAC}^2(Z) = \hat{\gamma}_0 + 2 \sum_{k=1}^L \left(1 - \frac{k}{L+1} \right) \hat{\gamma}_k,$$

with $\hat{\gamma}_k$ the sample autocovariances of Z and L the bandwidth. Under stationarity, mixing, moment and long-run-variance consistency conditions the studentized statistic $\sqrt{N} \widehat{SSR}$, with $N = T - \tau + 1$ the number of rolling windows, is asymptotically standard normal under the boundary null, and the authors recommend a moving block bootstrap for finite-sample

inference because the overlap-induced dependence makes the asymptotic approximation unreliable. Their hedge fund results range from 0.27 to 0.62 with a 36-month window and an Andrews (1991) bandwidth that selected 15 lags; the Newey and West (1994) rule selected 5 lags on the same data, with SSR levels 34 percent lower under Andrews and a rank correlation of 0.98 between the two. They document that rankings survive changes of window and bandwidth while levels do not, and that stability is conditional on the regime: across three subperiods of their sample the cross-sectional rank correlation of SSR averages 0.31.

SSR measures the average rolling Sharpe ratio relative to its long-run standard deviation, combining performance level, dispersion and serial dependence in one number. Two hedge fund indices with nearly identical Sharpe ratios in their sample (Merger Arbitrage at 1.73 and Equity Market Neutral at 1.72) have SSRs of 0.62 and 0.40. The authors recommend a benchmark Sharpe ratio $SR^* = 0$ for empirical use because the ratio's elasticities diverge as the benchmark approaches the mean rolling Sharpe ratio, define a Credibility-Adjusted SSR as the product of SSR and the Probabilistic Sharpe Ratio, and note that SSR is the more useful of the two when the Probabilistic Sharpe Ratio already exceeds 0.95.

3. Data

3.1 The catalog and the sample

BestFolio maintains a catalog of rules-based asset allocation strategies, each with one or more parameter variants, and publishes for each variant a full-history backtest, periodic signals and summary statistics. The extract used here was taken from the production database on 5 September 2026 (release release/2026-09-05-8b44fa1). At that date the catalog held 219 active variants, of which 177 were published on the public leaderboard and 42 were research variants that were tested but not published at the time of extraction. All 219 enter the Deflated Sharpe Ratio's count of trials.

The primary sample is the published set less two restrictions. First, three variants of one strategy whose macroeconomic input is known to have been reconstructed with revised rather than point-in-time data are excluded pending restatement; the supplementary file identifies them. Second, the SSR is reported only for variants with at least 120 completed monthly returns, which excludes one further variant with 84 months. The primary sample therefore holds 173 variants from 92 strategy families. Section 6.3 reports the sensitivity of the headline statistics to the first restriction: including the three excluded variants changes the median SSR by less than 0.01 and the adjacent-decade rank correlations by less than 0.01.

The strategies fall into two types. Tactical variants (142) change their allocation on a schedule according to momentum, trend, breadth, volatility or macroeconomic rules; they include reconstructions of the Global Tactical Asset Allocation family (Faber, 2007), Global Equities Momentum (Antonacci, 2014), and the Protective, Vigilant, Defensive, Bold and Hybrid Asset Allocation family (Keller and Keuning, 2016, 2017, 2018, 2022, 2023), as well as house strategies and community-contributed variants. Static variants (31) are fixed-weight allocations rebalanced on a schedule, from the classic 60/40 to the Permanent Portfolio, the Golden Butterfly and All Weather. By rebalancing frequency there are 121 monthly, 24 daily, 17 annual, 10 quarterly and 1 weekly variants; 52 use leveraged exchange-traded funds or synthetic

leverage. Variants of one strategy share rules and often assets, so the 173 series are not independent draws; two variants (a US-equity-only allocation listed under two strategy names) share an identical return path over the last decade. We report the catalog as published and note where family structure matters.

3.2 Series construction and conventions

Every backtest is simulated daily by the platform's engine on adjusted prices. The platform's published methodology states one-way transaction costs of 10 basis points and execution on the session after a signal; the study uses the stored net asset value series and does not re-run the engine. Where an instrument's history is shorter than the backtest, the engine substitutes documented proxies (index funds, futures-based series, or synthetic leverage built from an index), so the earliest histories reach back to the 1920s. Between signals the engine holds the resulting positions and lets weights drift; at a signal it trades to the new target weights, and the one-way turnover reported for a variant is half the sum of absolute weight changes at each signal, summed over a year and averaged over the backtest. Single-asset regimes therefore trade only when their signal flips, static allocations only on their rebalancing schedule, and monthly rotations at most once a month.

The stability statistic is computed on monthly returns from completed month-end observations. The extract ends on 3 or 4 September 2026 depending on the series; we drop that partial month and use returns through 31 August 2026. The platform's own published Stability column keeps the current partial month, following its published Sharpe convention; the rank correlation between the two treatments across the 173 variants is 0.9999, the largest difference in any variant's SSR is 0.013, and the median is 0.438 under both. Of the 173 variants, 34 start before 1980, 144 before 1990, 166 before 2000 and 172 before 2008; the median history is 486 months and the longest 1,274.

Returns are used with a cash reference of zero, as in the platform's published Sharpe convention: the rolling Sharpe ratio is the mean of raw monthly returns over their standard deviation, not of excess returns over a cash rate. Across a century of changing short rates this raises Sharpe levels in high-rate decades relative to an excess-return definition; every series is treated the same way, and we flag it as a limitation in Section 9. The monthly moments used for the Probabilistic Sharpe Ratio are recomputed from the same returns; the stored monthly Sharpe ratios on the platform agree with the recomputed ones to within 0.002 per month. The Deflated Sharpe Ratio, compound growth rate, maximum drawdown and turnover are imported from the platform's leaderboard payload as published on 5 September 2026 and are not recomputed.

Benchmarks are constructed from the same price database: the Vanguard 500 Index Fund (VFINX, from August 1976) as the S&P 500 proxy, the Vanguard Total Bond Market Index Fund (VBMFX, from December 1986) for US bonds, a monthly-rebalanced 60/40 blend of the two, and the gold (GLD, from November 2004), long Treasury (TLT from July 2002, VUSTX from May 1986) and Nasdaq 100 (QQQ, from March 1999) funds. Their windows are stated with every number.

3.3 The platform's Deflated Sharpe Ratio

The Deflated Sharpe Ratio published for each variant counts the 219 active variants as trials ($K=219$), takes the cross-trial variance of monthly Sharpe ratios from that same set, and uses each variant's own history length and monthly moments in the Bailey and López de Prado (2014) formula. The resulting no-skill benchmark is an annualised Sharpe ratio of 0.56. Treating catalog entries as independent trials overstates the effective number of trials, since variants of one strategy are correlated; raw K is a modelling choice, not a validated search correction, and Section 7 treats the score as published rather than as a corrected probability. The published values carry six decimals: among the 173 variants there are 158 distinct values, 10 equal to one exactly, and 88 that round to 1.00 at two decimals.

4. Methodology

4.1 Estimator

For each series we compute monthly simple returns $r_1, \dots, r_T$ from completed month-end net asset values. With window $\tau=36$ the rolling per-period Sharpe ratio is

$$Z_t = \frac{\hat{r}_{t,\tau}}{\hat{\sigma}_{t,\tau}}, \hat{\sigma}_{t,\tau}^2 = \frac{1}{\tau-1} \sum_{j=0}^{\tau-1} (r_{t-j} - \hat{r}_{t,\tau})^2, t = \tau, \dots, T,$$

with the zero cash reference of Section 3.2 and no annualisation, which cancels in the ratio. Reindex the rolling process as $Z_1, \dots, Z_N$ with $N = T - \tau + 1$, let $\bar{Z}$ be its mean, and let

$$\hat{\gamma}_k = \frac{1}{N} \sum_{t=k+1}^N (Z_t - \bar{Z})(Z_{t-k} - \bar{Z}), \hat{\sigma}_L^2 = \hat{\gamma}_0 + 2 \sum_{k=1}^L \left(1 - \frac{k}{L+1}\right) \hat{\gamma}_k$$

be the sample autocovariances with divisor N and the Bartlett-kernel long-run variance with bandwidth L . The reported statistic is $\widehat{SSR} = \bar{Z} / \hat{\sigma}_L$ with benchmark $SR^* = 0$ and $L = \tau - 1 = 35$. Throughout, K denotes trials, T monthly returns, N rolling estimates and ℓ the bootstrap block length.

The statistic is a fixed-bandwidth descriptive analogue of the structural SSR rather than a consistent estimate of it. A fixed bandwidth does not in general estimate the infinite-horizon variance consistently, and the Bartlett weights recover only part of the overlap-induced dependence even when the bandwidth spans it: under the mechanical-overlap approximation

of Proposition 3.1 with $\tau=36$, the long-run variance ratio $\sigma_\infty^2 / \gamma_0 \approx 1 + 2 \sum_{k=1}^{35} (1 - k/36) = 36$,

whereas the Bartlett estimate with $L=35$ approaches $1 + 2 \sum_{k=1}^{35} (1 - k/36)^2 \approx 24$, so the fixed-

bandwidth SSR sits roughly 22 percent above the structural target under that approximation. We therefore do not apply the source paper's standard-normal calibration to this specification, and we present the statistic as a ranking aid whose levels are specific to the window and bandwidth stated.

The statistic is reported as missing, by policy rather than mathematical necessity, when fewer than 120 monthly returns are available; it is undefined when any rolling window has a standard deviation at or below 10^{-12} or when the long-run variance is not positive. At the gate $N=85$ and $L/N \approx 0.41$; the ten-year threshold is a reporting choice and has not been calibrated in finite samples. In the primary sample the shortest history is 220 months, so the results say little about behaviour near the gate.

4.2 Bandwidth

The source paper selects the bandwidth with the Andrews (1991) automatic procedure, which returned $L=15$ on all seventeen of its 29-year monthly series, and reports that the Newey and West (1994) rule returns $L=5$ on the same data, with SSR levels 34 percent lower under Andrews and a rank correlation of 0.98 between the two. We have not implemented Andrews' procedure. For a comparative table we prefer one fixed specification for all series, $L=\tau-1=35$, the full extent of the mechanical overlap, so that every strategy is measured by the same estimator and the levels are reproducible from the definition alone. Section 6.3 reports the sensitivity to $L \in \{5, 15, 35, 71\}$ and to the sample-size rule $L = \lfloor 4(N/100)^{2/9} \rfloor$, which selects 4 to 6 lags on these series (7, 154 and 12 variants respectively) and which we call the sample-size rule to distinguish it from the full data-dependent Newey and West (1994) procedure. The fixed 35-lag specification produces lower point estimates than the fixed 5- and 15-lag specifications and the sample-size rule; we have not established conservative inferential coverage for it, and increasing the bandwidth further does not lower every variant's value.

4.3 Bootstrap

We follow the source paper's recommendation and use a moving block bootstrap (Künsch, 1989): contiguous blocks of ℓ monthly returns are drawn with replacement from the original series and concatenated to its length, the rolling process and the fixed-bandwidth SSR are recomputed on each replicate, and $B=2,000$ replicates are summarised. Rather than the automatic block length of Politis and White (2004), as corrected by Patton, Politis and White (2009), we report two fixed lengths, $\ell=12$ and $\ell=36$ months; results are reported for $\ell=36$ and checked against $\ell=12$. Resampling return blocks and recomputing the rolling statistic recreates the mechanical overlap dependence, but a block equal to the window length does not preserve the original regime structure, and we make no claim that it does.

For each variant we report the 2.5th and 97.5th percentiles of the replicates (the percentile interval), the basic interval $[2\widehat{SSR} - q_{0.975}, 2\widehat{SSR} - q_{0.025}]$, and the uncentered bootstrap proportion $q_{\leq c} = B^{-1} \sum_b 1\{\widehat{SSR}^{i(b)} \leq c\}$ for $c=0.5$. The proportion is not a posterior probability and is not generated under a null; its only inferential reading is through the one-sided percentile bound, rejecting $H_0: SSR \leq c$ when the 5th bootstrap percentile exceeds c , subject to the method's coverage, which we have not validated. The Monte Carlo standard error of a tail proportion of 0.05 with $B=2,000$ is about 0.005.

4.4 Companion statistics and verification

For every variant we also compute the platform's Sharpe ratio (annualised mean over annualised sample deviation of the same monthly returns, zero cash reference), the

Probabilistic Sharpe Ratio at benchmark zero from the same monthly moments, the Credibility-Adjusted SSR of the source paper, and, for the principal comparisons, the components $\hat{Z}$, the naive standard deviation of Z and its HAC standard deviation. The published Deflated Sharpe Ratio, turnover, strategy type, rebalancing frequency, leverage and risk category are taken from the leaderboard payload.

The statistic was implemented twice: in a standalone script written from the definitions above, and in the platform's production service, written independently from a specification of the same definitions and tested against a hand-derived fixture. On identical inputs (the extract with the partial month, as served by the platform) the two agree to 15 decimals on 217 of the 219 active variants, the remaining two being below the production gate; the check is retained with the replication package. The standalone script also reproduces the platform's published Deflated Sharpe Ratios to within 0.00043.

5. Cross-sectional results

5.1 Distribution and resolution

Table 1 summarises the distribution of the full-history SSR across the 173 variants. Values run from 0.15 to 0.98 with a median of 0.44; 55 variants have an SSR of at least 0.5, 12 at least 0.7, and 16 fall below 0.3. Figure 1 shows the distribution against the two main benchmarks: the S&P 500 sits at 0.30 and the 60/40 blend at 0.34, both in the bottom quartile of the catalog.

Table 1. Distribution of the full-history SSR, 173 published variants, completed months through August 2026.

Statistic	Value
Minimum	0.15
10th percentile	0.31
25th percentile	0.36
Median	0.44
75th percentile	0.53
90th percentile	0.66
Maximum	0.98
Distinct values at two decimals	55 (Deflated Sharpe Ratio: 30)
Variants at or above 0.5 / 0.7	55 / 12

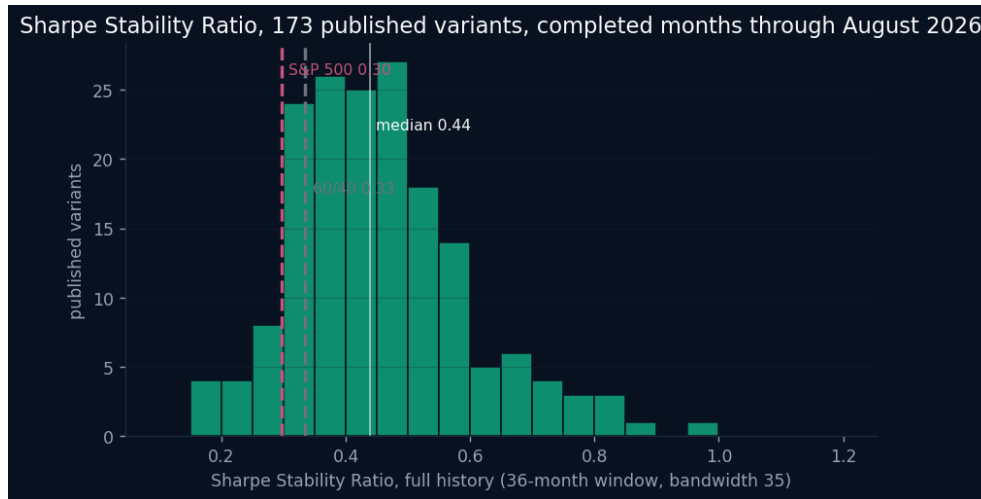

Figure 1. Distribution of the full-history SSR across the 173 published variants (histories start between 1920 and 2008 and end in August 2026; 36-month window, bandwidth 35), with the S&P 500 (VFINX, from 1976) and the 60/40 blend (from 1987) marked.

At two decimals the SSR takes 55 distinct values across the 173 variants and the Deflated Sharpe Ratio 30, with 88 variants rounding to 1.00. The published Deflated Sharpe Ratio retains more information than its rounded display suggests (158 distinct values at six decimals, of which 10 are exactly one), so the comparison is one of resolution at the precision commonly displayed rather than of the underlying statistics.

5.2 Relation to level and to credibility

Table 2 reports Spearman rank correlations between SSR and the companion statistics. The correlation with the Sharpe ratio is 0.67, indicating imperfect rank concordance. Figure 2 shows the joint distribution with a few named strategies. The correlations with the Deflated Sharpe Ratio and the Probabilistic Sharpe Ratio are 0.61 and 0.47; their differences from the Sharpe correlation may reflect sample length, higher moments and numerical ties. SSR is only weakly related to the level of return (0.20 with the compound annual growth rate) and moderately to the depth of the worst drawdown (0.49; shallower drawdowns go with higher SSR).

Table 2. Spearman rank correlation of the full-history SSR with companion statistics, 173 published variants.

Companion statistic	Rank correlation with SSR
Sharpe ratio	0.67
Deflated Sharpe Ratio	0.61
Probabilistic Sharpe Ratio at zero	0.47
Maximum drawdown (less negative is higher)	0.49
Annual turnover	0.31
Compound annual growth rate	0.20

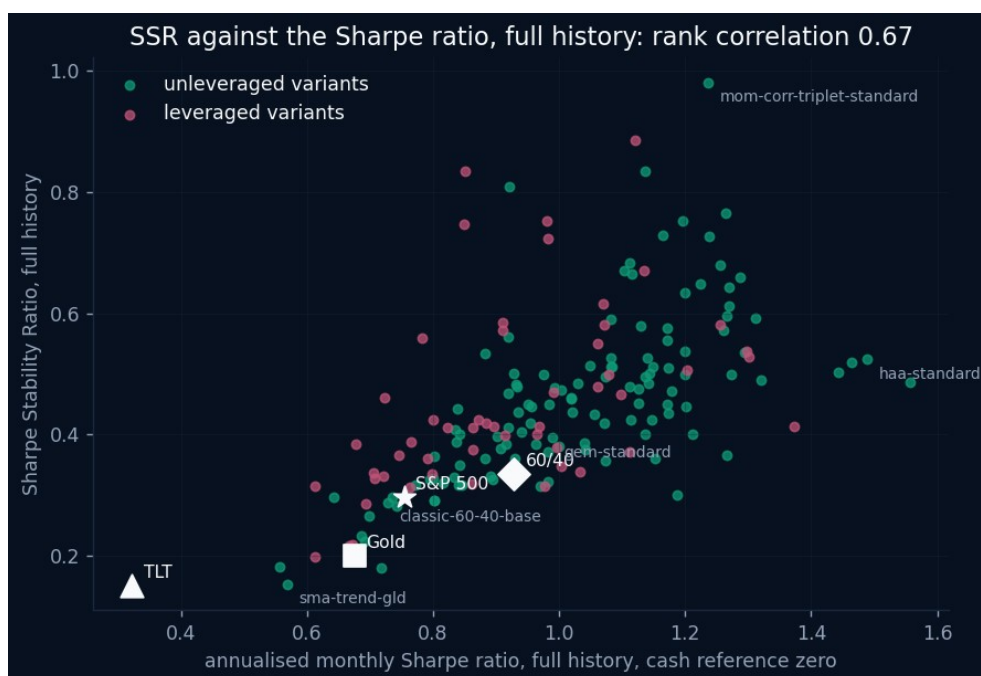

Figure 2. Full-history SSR against the annualised monthly Sharpe ratio (zero cash reference), 173 published variants, benchmarks marked. Rank correlation 0.67.

5.3 Groups

Table 3 gives medians by strategy type, rebalancing frequency, leverage and risk category, with every category shown so that the counts reconcile. Tactical variants have a higher median SSR than static ones (0.45 against 0.37), and the difference holds at both quartiles. Among frequency groups with more than one variant, monthly-rebalanced strategies have the highest median (0.47); daily strategies (0.37) and annually rebalanced allocations (0.34) the lowest; the single weekly variant scores 0.81. Leveraged variants have a slightly lower median than unleveraged ones (0.41 against 0.45). By the platform's risk category the medians are 0.50, 0.47 and 0.38 for conservative, moderate and aggressive variants. These ratios alone do not identify the contribution of numerator and denominator; for the record, the median annualised mean rolling Sharpe ratio is 1.18, 1.11 and 0.93 in the same three groups, so the aggressive group has both a lower average rolling Sharpe ratio and a lower SSR.

Table 3. Median full-history SSR by group (interquartile range in brackets), 173 published variants.

Group	n	Median SSR
Tactical	142	0.45 [0.38, 0.54]
Static	31	0.37 [0.32, 0.47]
Monthly rebalancing	121	0.47 [0.39, 0.54]
Weekly rebalancing	1	0.81
Quarterly rebalancing	10	0.41 [0.35, 0.47]
Daily rebalancing	24	0.37 [0.32, 0.41]

Group	n	Median SSR
Annual rebalancing	17	0.34 [0.32, 0.47]
Unleveraged	121	0.45 [0.36, 0.52]
Leveraged	52	0.41 [0.35, 0.54]
Conservative risk	16	0.50 [0.43, 0.51]
Moderate risk	105	0.47 [0.37, 0.54]
Aggressive risk	46	0.38 [0.33, 0.42]
No risk category	6	0.47 [0.41, 0.53]

5.4 The extremes

Table 4 lists the twelve highest and twelve lowest full-history SSR values. The top is dominated by monthly momentum rotations with diversified defensive legs: the Momentum-Correlation Triplet family (0.83 to 0.98), the DMS Triad family (0.68 to 0.77), Pragmatic Asset Allocation (0.73) and the KISS momentum blends (0.62 to 0.73). The bottom is a mix of single-asset trend rules on bonds and gold (0.15 to 0.18), daily volatility-regime strategies (0.20 to 0.22), a gold-based cross-asset rule (0.22) and static allocations (the classic 60/40 and a static leveraged three-asset mix at 0.29, a global 60/40 at 0.28). The three century-long series, Paired Switching and UIS from 1920 and the classic 60/40 from 1923, all sit in the bottom twelve on full history.

Table 4. Highest and lowest full-history SSR among the 173 published variants. Sharpe is the annualised monthly-mean ratio with a zero cash reference; DSR the published Deflated Sharpe Ratio; the interval is the 95 percent percentile moving block bootstrap interval with 36-month blocks.

Variant	From	Sharpe	DSR	SSR	95% interval	Turnover
Triplet, standard	1987	1.24	1.000	0.98	[0.44, 1.11]	3.8
Triplet, 1.5x leverage	1987	1.12	0.999	0.89	[0.40, 0.99]	4.7
Triplet, plus	1986	1.14	1.000	0.83	[0.39, 0.94]	4.8
Low-Initiative LETF v2	2002	0.85	0.921	0.83	[0.33, 0.99]	14.6
AlphaOne Momentum	1993	0.92	0.984	0.81	[0.42, 1.04]	13.9

Table 5 shows the same statistics for a set of widely followed strategies, with the components of the ratio for two of them. Hybrid Asset Allocation, the highest-Sharpe strategy in the table at 1.49, has a full-history SSR of 0.52: all 595 of its rolling estimates are positive, with a minimum annualised value of 0.25, and its annualised mean rolling Sharpe ratio is 1.57, but the HAC standard deviation of the rolling series (0.86 in per-period units) is five times its naive standard deviation (0.17), and it is the HAC figure that the ratio divides by. Its SSR on the window since 2000 is 0.88. The Momentum-Correlation Triplet has a lower mean rolling Sharpe ratio (1.21 annualised) and a much lower HAC standard deviation (0.36), which is what puts it at the top. Global Equities Momentum, with a Sharpe ratio of 0.99, has an SSR of 0.39 and a bootstrap proportion of 0.90 at or below 0.5. The Golden Butterfly and the classic 60/40 have Sharpe ratios comparable to several tactical strategies and lower SSRs, which is the pattern the group medians summarise.

Table 5. Selected widely followed strategies. Sharpe and DSR are full-history; SSR is shown for the full history and for windows starting in January 2000 and January 2008; the final column is the proportion of 36-month-block bootstrap replicates at or below 0.5 for the full-history estimate, an uncentered proportion whose one-sided reading depends on the method's coverage (Section 4.3).

6. Period sensitivity and robustness

6.1 Benchmarks and the evaluation window

Table 6 reports the SSR of the benchmarks on the full available history and on windows starting in January 2000 and January 2008, both ending in August 2026. On the full history and on the 2000 window the S&P 500 scores 0.30 and 153 of the 166 published variants with data over that window exceed it. On the 2008 window the S&P 500 scores 0.74, the Nasdaq 100 0.88 and the 60/40 blend 0.60, and 55 of 172 variants exceed the S&P 500. Figure 3 illustrates the two rolling Sharpe paths behind one pair of numbers, Hybrid Asset Allocation and the S&P 500: the first never crossed zero and the second did twice, in 2000 to 2003 and 2008 to 2010, before holding high for a decade. The figure shows the paths; it does not measure the return cost of defensive positioning, and Table 7 does not either.

Table 6. SSR of benchmark series on three windows, all ending in August 2026. The 2000 and 2008 windows are shown only where the series covers them from the start.

Series	From	Sharpe	SSR full	2000 on	2008 on
S&P 500 (VFINX)	1976	0.75	0.30	0.30	0.74
60/40 (VFINX/VBMFX)	1987	0.93	0.34	0.35	0.60
US bonds (VBMFX)	1987	1.00	0.32	0.30	0.23
Long Treasuries (VUSTX)	1986	0.50	0.23	0.19	0.12
Nasdaq 100 (QQQ)	1999	0.56	0.27	0.30	0.88
Gold (GLD)	2004	0.67	0.20	n/a	0.17

Series	From	Sharpe	SSR full	2000 on	2008 on
Long Treasuries (TLT)	2002	0.32	0.15	n/a	0.11
Variants above the S&P 500				153 of 166	55 of 172
Variants above 60/40				136 of 166	98 of 172

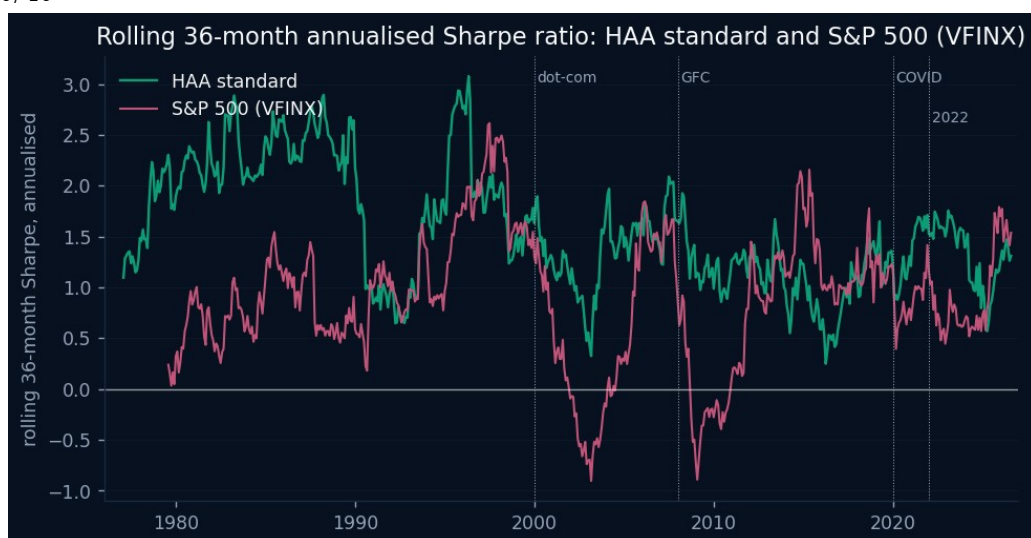

Figure 3. Rolling 36-month annualised Sharpe ratio of Hybrid Asset Allocation (rolling series from February 1977) and the S&P 500 proxy VFINX (from August 1979), through August 2026.

Figure 4 plots each variant's SSR on the 2000 window against its SSR on the 2008 window for the 166 variants that have both. The rank correlation between the two windows is 0.53, and between the full history and the 2008 window 0.36 (0.80 for the 2000 window, which shares most of its history with the full sample). Relative rankings change between overlapping evaluation windows; group comparisons should use common dates and a common eligible cohort, and Table 7 does so.

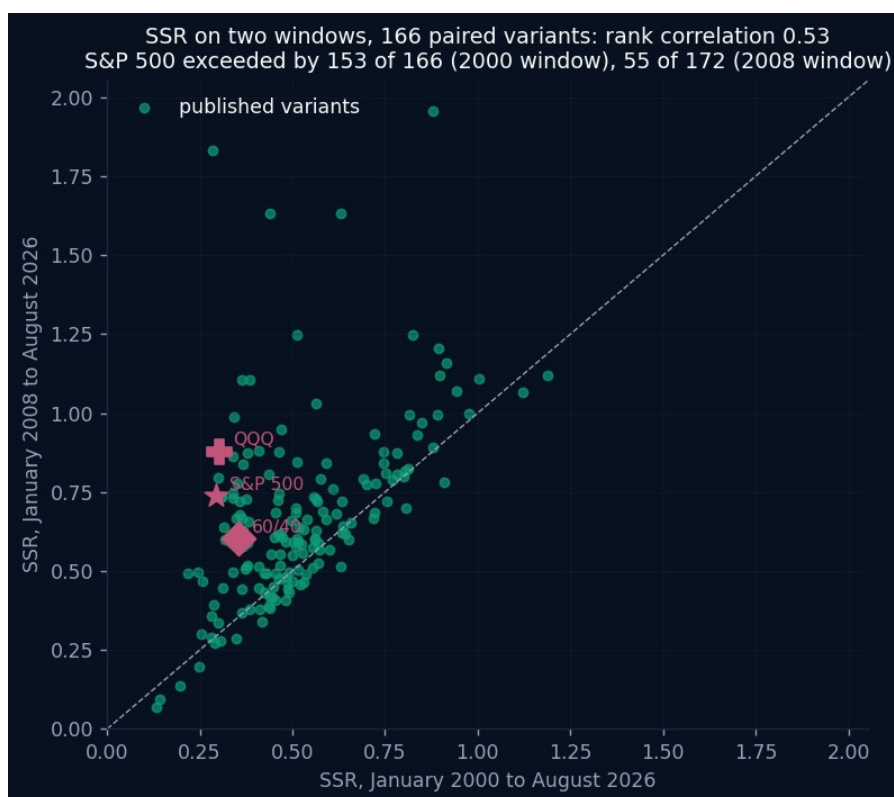

Figure 4. SSR on the January 2000 to August 2026 window against SSR on the January 2008 to August 2026 window, 166 paired variants, benchmarks marked. The counts in the title refer to the larger cohorts of Table 6.

6.2 Subperiods

To examine whether the cross-sectional ordering persists, we split the calendar into four subperiods, before 2000, 2000 to 2009, 2010 to 2019, and January 2020 to August 2026, and recompute the SSR inside each for every published variant with at least 72 monthly returns in it. The cohorts hold 160, 172, 173 and 174 variants; the last includes the 84-month variant excluded from the full-history tables. The last subperiod holds 80 completed monthly returns and 45 rolling estimates, the 2010s exactly 120 returns for every variant, and the pre-2000 period between 73 and 954 returns depending on the variant. The subperiods are therefore not four equivalent decades. Table 7 reports the medians, the benchmarks and the cross-sectional rank correlations between subperiods with their pairwise sample sizes.

Table 7. SSR by subperiod: medians across published variants (72-month minimum, so levels are not comparable with the full-history values), medians by strategy type, benchmark values (TLT's 2000s value rests on 89 returns), and Spearman rank correlations of the cross-section between subperiods (pairwise n in brackets).

	Before 2000	2000 to 2009	2010 to 2019	2020 to Aug 2026
Variants with an estimate	160	172	173	174
Median SSR, all	0.66	0.82	1.02	0.82

	Before 2000	2000 to 2009	2010 to 2019	2020 to Aug 2026
Median SSR, tactical	0.64	0.94	0.88	0.99
Median SSR, static	0.70	0.36	1.58	0.63
S&P 500 (VFINX)	0.40	0.15	1.63	0.81
60/40 (VFINX/VBMFX)	0.63	0.23	1.60	0.59
US bonds (VBMFX)	0.62	1.05	0.78	−0.03
Long Treasuries (TLT, from Aug 2002)	n/a	3.38	0.80	−0.47
Nasdaq 100 (QQQ)	n/a	0.13	2.23	0.70
Rank correlation with before 2000		−0.04 (160)	−0.02 (160)	−0.13 (160)
Rank correlation with 2000 to 2009			−0.43 (172)	−0.07 (172)
Rank correlation with 2010 to 2019				0.08 (173)

Between adjacent subperiods the rank correlation of the cross-section is -0.04 , -0.43 and 0.08 . Higher estimated SSR in the 2000s is associated with lower estimated SSR in the 2010s; this is an imperfect association rather than a complete reversal, and it is not an artefact of the bandwidth: the 2000s-to-2010s correlation is -0.39 , -0.40 , -0.43 and -0.31 under $L=5, 15, 35$ and 71 . The benchmarks move with it. The S&P 500 goes from 0.15 to 1.63 between the two decades and the 60/40 blend from 0.23 to 1.60 , while the median static variant goes from 0.36 to 1.58 and the median tactical variant from 0.94 to 0.88 ; in the 2020 window the ordering of the two types reverses again (0.99 against 0.63). The results are consistent with period dependence in estimated SSR, but differences in samples, estimators and estimation uncertainty prevent a stronger comparison with the hedge fund findings of Bajo Traver and Rodriguez Dominguez (2026), whose average subperiod rank correlation is 0.31 .

Several explanations remain to be separated, and the design here does not separate them: finite-sample variability of the estimated denominator when the period holds few rolling estimates (at most 45 in the last subperiod against a 35-lag bandwidth), the removal of between-regime variation when the period is short, the restarting of rolling windows at each boundary, unequal history lengths across variants within a period, and genuine changes in how strategies behaved. Short subperiods create uncertainty in both levels and rankings. Ordinary standard errors for these rank correlations would also be inappropriate, because the variants share returns and belong to related families; we report the correlations as descriptive statistics with their sample sizes.

6.3 Window, bandwidth and sample sensitivity

Table 8 reports the sensitivity of the cross-section to the rolling window and to the HAC bandwidth. The first four rows change the window and the bandwidth together ($L = \tau - 1$), as the definition does; the next two hold the bandwidth at 35 and change the window alone. Rankings are similar across windows of 24, 36, 48 and 60 months (rank correlation 0.96 , 0.98 and 0.98 between adjacent lengths; 0.86 between 24 and 60) and levels rise with the window (medians 0.42 to 0.47), as in the source paper. The bandwidth moves levels much more: the median SSR is 0.87 with 5 lags, 0.58 with 15, 0.44 with 35 and 0.41 with 71, and the sample-size

rule gives 0.87. Rank correlations with the 35-lag baseline are 0.98, 0.99, 0.94 and 0.98, but individual variants can move substantially: one moves 49 places between the 35- and 71-lag specifications. Comparisons should state both window and bandwidth choices, and high aggregate rank correlations in this sample do not guarantee agreement for individual strategies or other datasets.

Table 8. Sensitivity of the cross-section to the rolling window and the HAC bandwidth, 173 published variants.

Specification	Median SSR	Rank correlation with baseline
Window 24 months, bandwidth 23	0.42	0.96 (with 36/35)
Window 36 months, bandwidth 35 (baseline)	0.44	1.00
Window 48 months, bandwidth 47	0.45	0.98 (with 36/35)
Window 60 months, bandwidth 59	0.47	0.94 (with 36/35)
Window 24 months, bandwidth 35	0.41	0.99
Window 60 months, bandwidth 35	0.54	0.97
Window 36 months, bandwidth 5	0.87	0.98
Window 36 months, bandwidth 15	0.58	0.99
Window 36 months, bandwidth 71	0.41	0.94
Window 36 months, sample-size rule (4 to 6 lags)	0.87	0.98

The two sample restrictions of Section 3 matter little for the aggregates. Including the three excluded variants of the revised-data strategy gives 176 variants, a median of 0.44, 58 variants at or above 0.5, a rank correlation with the Sharpe ratio of 0.67 and a 2000s-to-2010s rank correlation of -0.42 . Keeping the partial September 2026 observation, as the platform's public column does, leaves the median at 0.44, moves the count at or above 0.5 from 55 to 57, and gives a rank correlation of 0.9999 with the completed-month values.

6.4 Bootstrap intervals

Figure 5 shows the 95 percent percentile intervals for the twelve highest and twelve lowest variants. All 173 percentile intervals exclude zero under both block lengths. This concerns positive mean rolling performance: it does not test whether temporal stability exceeds what rolling estimation on a constant positive Sharpe ratio would produce, which would require a simulation we have not run. No variant's 5th bootstrap percentile exceeds 0.5, and 9 variants have percentile intervals that lie entirely below 0.5. The median interval width is 0.45.

The bootstrap distributions are not centred on the point estimates for the steadiest strategies. Across the catalog the median ratio of bootstrap mean to point estimate is 1.03, but for the Momentum-Correlation Triplet the bootstrap mean is 0.69 against a point estimate of 0.98, and its percentile interval $[0.44, 1.11]$ and basic interval $[0.85, 1.53]$ give opposite answers about 0.5; for Hybrid Asset Allocation the bootstrap mean is 0.62 against 0.52, with intervals $[0.44, 0.87]$ and $[0.18, 0.61]$. Block resampling breaks the long regime structure that produces the highest SSR values, so the intervals are reported as descriptive and no coverage is claimed. Marginal intervals also say nothing about the uncertainty of differences between neighbours or of ranks,

which would require synchronised resampling across strategies. The qualitative pattern, intervals that exclude zero but not 0.5, resembles the source paper’s hedge fund findings, although the estimators, bootstrap designs and significance levels differ.

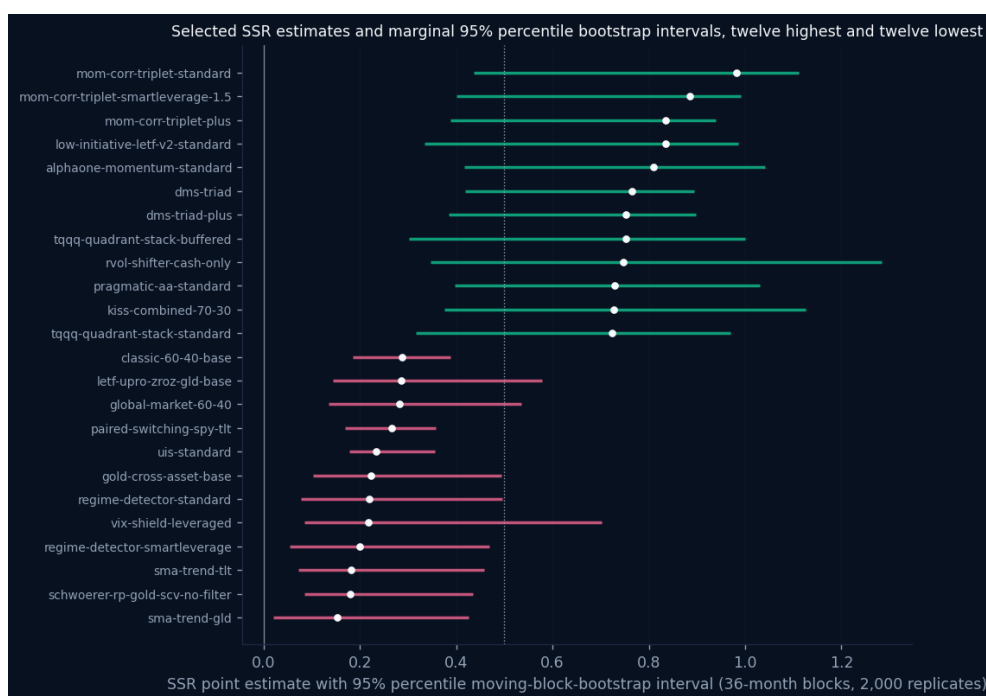

Figure 5. SSR point estimates with 95 percent percentile moving block bootstrap intervals (36-month blocks, 2,000 replicates), twelve highest and twelve lowest published variants.

7. The Deflated Sharpe Ratio and the SSR together

The Deflated Sharpe Ratio and the SSR answer different questions, and Table 9 shows that they classify the catalog differently at the thresholds the platform uses. Of the 173 variants, 146 carry a Deflated Sharpe Ratio of at least 0.90, the platform’s cutoff below which it flags a strategy as fragile. Of those 146, 54 have an SSR of at least 0.5 and 92 fall below that descriptive threshold. One variant has a Deflated Sharpe Ratio below 0.90 and an SSR of at least 0.5, and 26 fall below both thresholds. The chosen cutoffs produce different classifications in this selected catalog; neither classification establishes prospective credibility. The Credibility-Adjusted SSR of the source paper is numerically close to the SSR and produces identical ranks in this sample, because the Probabilistic Sharpe Ratio at zero is at least 0.9993 for every variant with a history this long.

Table 9. Joint classification of the 173 published variants by the published Deflated Sharpe Ratio (threshold 0.90) and the full-history SSR (threshold 0.5).

	SSR at or above 0.5	SSR below 0.5
DSR at or above 0.90	54	92
DSR below 0.90	1	26

8. Turnover

The unadjusted association between reported annual turnover and SSR is positive: the rank correlation is 0.31 across the 173 variants. Table 10 splits the variants into turnover terciles with a deterministic tie policy (turnover, then variant identifier). The lowest tercile (turnover up to 1.4 times the portfolio per year) has a median SSR of 0.41, the middle tercile (1.4 to 3.0) 0.41 and the highest tercile (3.0 to 14.6) 0.50, with median full-sample Sharpe ratios of 0.98, 1.00 and 1.00. Figure 6 shows the relation. The terciles differ substantially in composition: all 31 static variants and all 27 annually or quarterly rebalanced variants are in the lowest tercile, while the top tercile is entirely tactical and holds 24 of the 52 leveraged variants. Within tactical variants the rank correlation between turnover and SSR is 0.23 (142 variants), and within monthly tactical variants 0.17 (117 variants), so static membership does not explain the whole association, but these descriptive comparisons do not isolate a turnover effect: strategy type, rebalancing frequency, leverage and asset exposures all move with turnover. Persistent asset exposures may contribute to period differences in rolling Sharpe ratios, and a defensive leg may reduce them; testing that explanation requires holdings and return attribution across market conditions, which this paper does not attempt.

Table 10. Turnover terciles, 173 published variants, full history, with composition.

Tercile	Annual turnover range	n	Median SSR	Median Sharpe	Tactical / static	Monthly / daily / other
Lowest	0.0 to 1.4	57	0.41	0.98	26 / 31	23 / 7 / 27
Middle	1.4 to 3.0	57	0.41	1.00	57 / 0	50 / 7 / 0
Highest	3.0 to 14.6	59	0.50	1.00	59 / 0	48 / 10 / 1

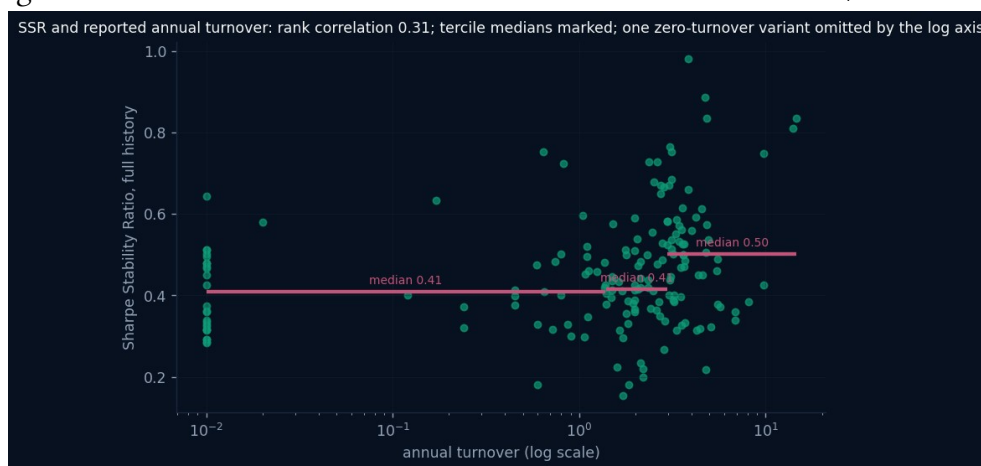

Figure 6. Full-history SSR against reported annual turnover (log scale; the one zero-turnover variant is omitted by the axis), tercile medians marked. Rank correlation 0.31.

9. Limitations

Every strategy series here is a backtest produced by one engine under one execution convention, and the benchmark series are constructed from observed fund prices. The catalog

is selected retrospectively: strategies entered it because their published or proposed backtests were attractive, its Deflated Sharpe Ratio represents a partial model of the recorded search and does not correct for catalog selection, for the searches upstream in the published research (Bailey, Borwein, López de Prado and Zhu, 2014; Harvey, Liu and Zhu, 2016), or for data errors, and the SSR inherits whatever look-ahead or proxy error the underlying series carry. Variants within a family are correlated and two share a return path, so cross-sectional counts overstate the number of independent strategies. Returns are used with a zero cash reference; an excess-return version would lower the rolling Sharpe ratios of high-rate decades and could change the ordering of strategies with different histories.

The estimator has two tuning choices, the window and the bandwidth. The bandwidth moves levels by a factor of two while leaving aggregate orderings largely intact, and the fixed 35-lag specification is a descriptive analogue rather than a consistent estimate of the structural ratio (Section 4.1); levels reported here should not be compared with levels computed under an automatic bandwidth rule. The bootstrap uses fixed block lengths, its distributions are biased for the steadiest strategies, and no coverage has been validated. The subperiod design compares unequal periods and cohorts, and the negative correlation between the 2000s and the 2010s, although robust to the bandwidth, has not been separated from estimation effects. Finally, the reported comparisons show no consistent positive rank persistence across the selected historical periods, but prospective predictive value remains untested. Such a test does not require live histories: it requires frozen rules, defensible publication dates, point-in-time inputs and genuinely withheld evaluation data, in the sense of the discovery and embargo samples of López de Prado, Lipton and Zoonekynd (2026), and the retrospective selection of the present catalog makes those safeguards necessary.

10. Conclusion

This selected catalog illustrates how estimated SSR rankings differ from Sharpe and Deflated Sharpe rankings and how they vary across historical evaluation periods. The statistic resolves ties among strategies whose Deflated Sharpe Ratios round to one, it is imperfectly correlated with the Sharpe ratio, and its aggregate rankings are stable across the tested windows and bandwidths although individual ranks can move substantially. Its most important property in this sample is period dependence: the relative SSR of tactical strategies, static allocations and equity benchmarks changes from one decade to the next, and the S&P 500 moves from the least stable series of the 2000s to among the most stable of the 2010s. That is not a flaw in the statistic. It is the statistic reporting, in one number, how different a strategy's risk-adjusted path looks depending on which regimes the window contains. Interpretation remains conditional on data provenance, sample selection and the estimator's finite-sample behaviour, and the SSR is best read, as its authors suggest, as a description of a track record rather than a forecast.

Disclosure

The author operates BestFolio, the platform whose catalog is analysed here, and has a commercial interest in it. The study used the platform's stored series and public API and

received no external funding. The statistic, its implementation and the data files are described in Appendix A so that the results can be checked independently.

Acknowledgements

We thank Roman Rubsamen of Portfolio Optimizer for bringing the Sharpe Stability Ratio to our attention, for the exposition on which our implementation notes draw, and for agreeing to be named; Mario Bajo Traver and Alejandro Rodriguez Dominguez for the statistic itself; and an adversarial machine review of an earlier draft, which caught several numerical and interpretive errors. Any remaining errors are ours.

Appendix A. Replication and provenance

Data. The month-end net asset value series of all 219 active variants and the adjusted month-end closes of the benchmark funds were extracted from BestFolio’s production database on 5 September 2026, when production ran release release/2026-09-05-8b44fa1; the leaderboard payload (Deflated Sharpe Ratio, turnover, strategy type, frequency, leverage, risk category) was taken from the public endpoint /api/performance/leaderboard on the same day. The frozen extracts, the study script that produced every number in this paper (ssr_paper_study_v2.py, Python with NumPy), the chart script, the hand-derived fixture used to test the production

implementation, the production-agreement check, and the supplementary tables are retained together as a replication package; a public archive will be linked from the abstract page. The supplementary variant table holds the 177 published variants with an exclusion flag (three revised-data variants, one below the ten-year gate) and, for each, the Sharpe ratio, Deflated Sharpe Ratio, Probabilistic Sharpe Ratio, the SSR on the full history and on the 2000 and 2008 windows, the four subperiods with their return counts, the four joint window-bandwidth specifications, the four fixed bandwidths and the sample-size rule, the components $\hat{Z}$, naive and HAC standard deviations, and the bootstrap mean, percentile and basic intervals and proportions for both block lengths.

Platform. The statistic is served on the platform's public leaderboard endpoint (`/api/performance/leaderboard`, field `sharpe_stability`, metadata `ssr_meta` with definition identifier `ssr-36m-nw-v1`) for every leaderboard period and currency, including the current partial month by the platform's convention, and on each strategy's summary endpoint for the full history in US dollars. The platform's methodology page documents the backtest conventions (transaction costs, execution timing, proxy chains) and the definition of the published Sharpe ratio.
